# Haskell Overloading (2)

A function like the identity function

id :: a -> a id x = x

is *polymorphic* precisely because it works uniformly for all types: there is no need to "inspect" the argument.

In contrast, to compare two "things" for equality, they very much have to be inspected, and an *appropriate method of comparison* needs to be used.

## Haskell Overloading (1)

What is the type of (==)?

E.g. the following both work:

1 == 2 'a' == 'b'

I.e., (==) can be used to compare both numbers and characters.

Maybe (==) :: a -> a -> Bool?

No!!! Cannot work uniformly for arbitrary types!

LiU-EP2010 Part II: Lecture 5 - p 2/27

LiU-EP2010 Part II: Lecture 5 - p.4/27

# Haskell Overloading (3)

Moreover, some types do not in general admit a decidable equality. E.g. functions (when domain infinite).

Similar remarks apply to many other types. E.g.:

- We may want to be able to add numbers of any kind
- But to add properly, we must understand what we are adding
- Not every type admits addition

## Haskell Overloading (4)

Idea:

- Introduce the notion of a type class: a set of types that support certain related operations.
- Constrain those operations to only work for types belonging to the corresponding class.
- Allow a type to be made an instance of (added to) a type class by providing type-specific implementations of the operations of the class.

# Instances of Eq(1)

Various types can be made instances of a type class like Eq by providing implementations of the class methods for the type in question:

```
instance Eq Int where
    x == y = primEqInt x y
instance Eq Char where
    x == y = primEqChar x y
```

## The Type Class Eq

class Eq a where
 (==) :: a -> a -> Bool

(==) is not a function, but a *method* of the *type class* Eq. It's type signature is:

(==) :: Eq a => a -> a -> Bool

Eq a is a *class constraint*. It says that that the equality method works for any type belonging to the type class Eq.

# Instances of Eq (2)

Suppose we have a data type:

data Answer = Yes | No | Unknown

We can make Answer an instance of Eq as follows:

instance Eq	Answer wh	lere
Yes	== Yes	= True
No	== No	= True
Unknown	== Unknow	n = True
_	==	= False

LiU-EP2010 Part II: Lecture 5 - p 5/27

LiU-EP2010 Part II: Lecture 5 - p.6/27

# Instances of Eq (3)

#### Consider:

```
data Tree a = Leaf a
            Node (Tree a) (Tree a)
```

#### Can Tree be made an instance of Eq?

### Instances of Eq (4)

Yes, for any type a that is already an instance of Eq: instance (Eq a) => Eq (Tree a) where Leaf al == Leaf a2 = a1 == a2Node t1l t1r == Node t2l t2r = t1l == t2l && t1r == t2r= False == \_

# **Derived Instances**

Instance declarations are often obvious and mechanical. Thus, for certain built-in classes (notably Eq. Ord, Show), Haskell provides a way to automatically derive instances, as long as

- the data type is sufficiently simple
- we are happy with the standard definitions

Thus, we can do:

```
data Tree a = Leaf a
            Node (Tree a) (Tree a)
           deriving Eq
```

LiU-EP2010 Part II: Lecture 5 - p.11/27

# **Class Hierarchy**

Type classes form a hierarchy. E.g.:

class Eq a => Ord a where (<=) :: a -> a -> Bool . . .

Eq is a superclass of Ord; i.e., any type in Ord must also be in Eq.

LiU-EP2010 Part II: Lecture 5 - p 10/27

## Haskell vs. OO Overloading (1)

A method, or overloaded function, may thus be understood as a family of functions where the right one is chosen depending on the types.

A bit like OO languages like Java. But the underlying mechanism is quite different and much more general. Consider read:

read :: (Read a) => String -> a

Note: overloaded on the *result* type! A method that converts from a string to *any* other type in class Read!

# **Implementation** (1)

The class constraints represent extra implicit arguments that are filled in by the compiler. These arguments are (roughly) the functions to use.

Thus, internally (==) is a *higher order function* with *three* arguments:

(==) eqF x y = eqF x y

### Haskell vs. OO Overloading (2)

```
> let xs = [1,2,3] :: [Int]
> let ys = [1,2,3] :: [Double]
> xs
[1,2,3]
> ys
[1.0,2.0,3.0]
> (read "42" : xs)
[42,1,2,3]
> (read "42" : ys)
[42.0,1.0,2.0,3.0]
> read "'a'" :: Char
'a'
```

# **Implementation** (2)

#### An expression like

1 == 2

is essentially translated into

(==) primEqInt 1 2

LiU-EP2010 Part II: Lecture 5 - p. 13/27

## **Implementation** (3)

So one way of understanding a type like

(==) :: Eq a => a -> a -> Bool

is that  $\mathbb{E}_{\mathbb{T}}$  a corresponds to an extra implicit argument.

The implicit argument corresponds to a so called directory, or tuple/record of functions, one for each method of the type class in question.

# Some Standard Haskell Classes (2)

class (Eq a, Show a) => Num a where

(+), (-), (*)	::	a -> a -> a	
negate	::	a -> a	
abs, signum	::	a -> a	
fromInteger	::	Integer -> a	

Quiz: What is the type of a numeric literal like 42? 42 :: Int? Why?

#### Some Standard Haskell Classes (1)

class Eq a where
 (==), (/=) :: a -> a -> Bool

class Show a where

```
show :: a -> String
```

# **Application: Automatic Differentiation**

- Automatic Differentiation: method for augmenting code so that derivative(s) computed along with main result.
- Purely algebraic method: arbitrary code can be handled
- Exact results
- But no separate, self-contained representation of the derivative.

LiU-EP2010 Part II: Lecture 5 - p 17/27

LiU-EP2010 Part II: Lecture 5 - p 18/27

### **Automatic Differentiation: Key Idea**

Consider a code fragment:

```
z1 = x + y
z2 = x * z1
```

Suppose the derivatives of x and y w.r.t. common variable is available in the variables x' and y'.

Then code can be augmented to compute derivatives of z1 and z2:

$$z1 = x + y$$
  
 $z1' = x' + y'$   
 $z2 = x * z1$   
 $z2' = x' * z1 + x * z1'$ 

**Functional Automatic Differentiation (1)** 

Introduce a new numeric type C: value of a continuously differentiable function at a point along with *all* derivatives at that point:

```
data C = C Double C
valC (C a _) = a
derC (C _ x') = x'
```

# Approaches

- Source-to-source translation
- Overloading of arithmetic operators and mathematical functions

The following variation is due to Jerzy Karczmarczuk. Infinite list of derivatives allows derivatives of *arbitrary* order to be computed.

# **Functional Automatic Differentiation (2)**

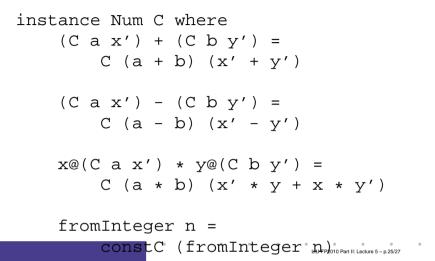

Constants and the variable of differentiation:

```
zeroC :: C
zeroC = C 0.0 zeroC
constC :: Double -> C
constC a = C a zeroC
dVarC :: Double -> C
dVarC a = C a (constC 1.0)
```

LiU-EP2010 Part II: Lecture 5 - p 22/27

#### **Functional Automatic Differentiation (3)**

#### Part of numerical instance:

# Reading

 Jerzy Karczmarczuk. Functional differentiation of computer programs. *Higher-Order and Symbolic Computation*, 14(1):35–57, March 2001.

### **Functional Automatic Differentiation (4)**

Computation of  $y = 3t^2 + 7$  at t = 2:

t = dVarC 2 y = 3 \* t \* t + 7

valC y	$\Rightarrow$	19.0
valC (derC y)	$\Rightarrow$	12.0
<pre>valC (derC (derC y))</pre>	$\Rightarrow$	6.0
<pre>valC (derC (derC (derC y)))</pre>	$\Rightarrow$	0.0
