**Abstract.** The efficient representation and manipulation of data is one of the fundamental tasks in the construction of large software systems. Parametric polymorphism has been one of the most successful approaches to date but, as of yet, has not been applicable to programming with quotient datatypes such as unordered pairs, cyclic lists, bags etc. This paper provides the basis for writing polymorphic programs over quotient datatypes by extending our recently developed theory of containers.

## 1 Introduction

The efficient representation and manipulation of data is one of the fundamental tasks in the construction of large software systems. More precisely, one aims to achieve amongst other properties: i) abstraction so as to hide implementation details and thereby facilitate modular programming; ii) expressivity so as to uniformly capture as wide a class of data types as possible; iii) disciplined recursion principles to provide convenient methods for defining generic operations on data structures; and iv) formal semantics to underpin reasoning about the correctness of programs. The most successful approach to date has been Hindley-Milner polymorphism which provides predefined mechanisms for manipulating data structures providing they are *parametric* in the data. Canonical examples of such parametric polymorphic functions are the `map` and `fold` operations which can be used to define a wide variety of programs in a structured and easy to reason about manner.

However, a number of useful data types and associated operations are not expressible in the Hindley-Milner type system and this has led to many proposed extensions including, amongst others, generic programming, dependent types (4), higher order types (6) shapely types (9), imaginary types (13) and type classes. However, one area which has received less attention is that of quotient types such as, for example, unordered

pairs, cyclic lists and the bag type. This is because the problem is fundamentally rather difficult — on the one hand one wants to allow as wide a theory as possible so as to encompass as many quotient types as possible while, on the other hand, one wants to restrict ones definition to derive a well behave meta-theory which provides support for key programming paradigms such as polymorphic programming etc.

This paper is, as far as we know, the first paper to give a detailed analysis of how to program with quotient types in a polymorphic fashion. In particular we

- We provide a syntax for declaring quotient datatypes which encompasses a variety of examples. This syntax is structural which we argue is essential for any theory of polymorphism to be applicable.
- We show how the syntax of such a declaration gives rise to a quotient datatype.
- We provide a syntax for writing polymorphic programs between these quotient datatypes and argue that these programs do indeed deserve to be called polymorphic.
- We show that every polymorphic function between our quotient datatypes is represented uniquely by our syntax. That is, our syntax captures all polymorphic programs in a unique manner.

To execute this program of research we extend our work on container datatypes (1; 2; 3). Container types represent types via a set of shapes and locations in each shape where data may be stored. They are therefore like Jay's shapely types (9) but more primitive as we discuss later. In previous papers cited above, we have shown how these container types are closed under a wide variety of useful constructions and can also be used as a framework for generic programming, eg they support a generic notion of differentiation. (3).

This paper extends containers to cover quotient datatypes by saying that certain labellings of locations with data are equivalent to others. We call these structures quotient containers. As such they correspond to the step from normal functors to analytic functors in Joyal's work (11). However, our quotient containers are more general than analytic functors as they allow infinite sets of positions to model coinductive datatypes. In addition, our definition of the morphisms between quotient containers is new as is all of their applications to programming. In addition, while pursuing the above program, we also use a series of running examples to aid the reader. We assume only the most basic definitions from category theory of category, functor and natural transformations. The exception is the use of left Kan extensions for which we supply the reader with the required information.

The paper is structured as follows. In section 2 we recall the basic theory of containers, container morphisms and their application to polymorphic programming. We also discuss the relationship between containers and shapely types. In section 3 we discuss how

quotient datatypes can be represented in container theoretic terms while in section 4 we discuss how polymorphic programs between quotient types can be represented uniquely as morphisms between quotient containers. We conclude in section 5 with some conclusions and proposals for further work.

## 2 A Brief History of Containers

**Notation:** Before we begin, some notation. We write  $\mathbb{N}$  for the set of natural numbers and if  $n \in \mathbb{N}$ , we write  $\underline{n}$  for the set  $\{0, \dots, n-1\}$ . We assume the basic definitions of category theory and if  $f : X \rightarrow Y$  and  $g : Y \rightarrow Z$  are morphisms in a category, we write their composite  $g \circ f : X \rightarrow Z$  as is standard categorical practice. We write  $K_1$  for the constantly 1 valued functor from any category to **Sets**. If  $A$  is a set and  $B$  is an  $A$  indexed family of sets, we write  $\Sigma a:A.B(a)$  for the set  $\{(a,b) \mid a \in A, b \in B(a)\}$ . We write  $!$  for the empty map from the empty set to any other set. Injections into the coproduct are written  $\text{inl}$  and  $\text{inr}$ .

This paper uses left Kan extensions to extract a universal property of containers which is not immediately visible. We understand that many readers will not be familiar with these structures so we supply all definitions and refer the reader to (12) for more details. Their use is limited to a couple of places and hence doesn't make the paper inaccessible to the non-cogniscenti. Given a functor  $I : \mathcal{A} \rightarrow \mathcal{B}$  and a category  $\mathcal{C}$ , precomposition with  $I$  defines a functor  $\_ \circ I : [\mathcal{B}, \mathcal{C}] \rightarrow [\mathcal{A}, \mathcal{C}]$ . The problem of left Kan extensions is the problem of finding a left adjoint to  $\_ \circ I$ . More concretely, given a functor  $F : \mathcal{A} \rightarrow \mathcal{C}$ , the left Kan extension of  $F$  along  $I$  is written  $\text{Lan}_I F$  defined via the natural isomorphism

$$[\mathcal{B}, \mathcal{C}](\text{Lan}_I F, H) \cong [\mathcal{A}, \mathcal{C}](F, H \circ I)$$

One can use the following coend formula to calculate the action of a left Kan extension when  $\mathcal{C} = \mathbf{Sets}$  and  $\mathcal{A}$  is small

$$(\text{Lan}_I F)X = \int_{A \in \mathcal{A}} \mathcal{B}(IA, X) \times FA$$

**What are Containers?** Containers capture the idea that concrete datatypes consist of memory locations where data can be stored. For example, any element of the type of lists  $\text{List}(X)$  of  $X$  can be uniquely written as a natural number  $n$  given by the length of the list, together with a function  $\{0, \dots, n-1\} \rightarrow X$  which labels each position within the list with an element from  $X$ :

$$n : \mathbb{N} , \quad f : \{0 \dots n-1\} \rightarrow X .$$

We may think of the set  $\{0, \dots, n-1\}$  as  $n$  memory locations while the function  $f$  attaches to these memory locations, the data to be stored there. Similarly, any binary tree can be uniquely described by its underlying shape (which is obtained by deleting the data stored at the leaves) and a function mapping the positions in this shape to the data thus:

More generally, we are led to consider datatypes which are given by a set of shapes  $S$  and, for each  $s \in S$ , a set of positions  $P(s)$  which we think of as locations in memory where data can be stored. This is precisely a container

**Definition 1 (Container).** A container  $(S \triangleright P)$  consists of a set  $S$  and, for each  $s \in S$ , a set of positions  $P(s)$ .

Of course, in general we do not want to restrict ourselves to the category of sets since we want our theory to be applicable to domain theoretic models. Rather, we would develop our theory over locally cartesian closed categories (7), certain forms of fibrations such as comprehension categories (8) or models of Martin-Löf type theory — our previous work (1; 2; 3) for such a development. However, part of the motivation for this paper was to make containers accessible to the programming community where we believe they provide a flexible platform for supporting generic forms of programming. Consequently, we have deliberately chosen to work over **Sets** so as to enable us to get our ideas across without an overly mathematical presentation.

As suggested above, lists can be presented as a container

**Example 2** The list type is given by the container with shapes given by the natural numbers  $\mathbb{N}$  and, for  $n \in \mathbb{N}$ , define the positions  $P(n)$  to be the set  $\{0, \dots, n - 1\}$ .

To summarise containers are our presentations of datatypes in the same way that data declarations are presentations of datatypes in Haskell. The semantics of a container is an endofunctor on some category which, in this paper, is **Sets**. This is given by

**Definition 3 (Extension of a Container).** Let  $(S \triangleright P)$  be a container. Its semantics, or extension, is the functor  $T_{S \triangleright P} : \mathbf{Sets} \rightarrow \mathbf{Sets}$  defined by

$$T_{S \triangleright P}(X) = \Sigma s \in S. (P(s) \rightarrow X)$$

An element of  $T_{S \triangleright P}(X)$  is thus a pair  $(s, f)$  where  $s \in S$  is a shape and  $f : P_s \rightarrow X$  is a labelling of the positions over  $s$  with elements from  $X$ . Note that  $T_{S \triangleright P}(X)$  really is a functor since its action on a function  $g : X \rightarrow Y$  sends the element  $(s, f)$  to the element  $(s, g \circ f)$ . Thus for example, the extension of the container for lists is the functor mapping  $X$  to

$$\Sigma n : \mathbb{N}. \{0, \dots, n - 1\} \rightarrow X .$$

Such pairs clearly bijectively correspond to lists.

The theory of containers was developed in a series of recent papers (1; 2; 3) which showed that containers encompass a wide variety of types as they are closed under various type forming operations such as sums, products, constants, fixed exponentiation, (nested) least fixed points and (nested) greatest fixed points. Thus containers encapsulate a large number of datatypes. So far, we have dealt with containers in one variable whose extensions are functors on **Sets**. The extension to  $n$ -ary containers, whose extensions are functors  $\mathbf{Sets}^n \rightarrow \mathbf{Sets}$ , is straightforward. Such containers consist of a set of shapes  $S$ , and for each  $s \in S$  there are  $n$  position sets  $P^n(s)$ . See the above references for details.

We finish this section with a more abstract presentation of containers which will be used to exhibit the crucial universal property that they satisfy. This universal property underlies the key result about containers. First, note that the data in a container  $S \triangleright P$  can be presented as a functor  $P : S \rightarrow \mathbf{Sets}$  where here we regard the set  $S$  as a discrete category and  $P$  maps each  $s$  to  $P(s)$ . In future, we will switch between these two views of a container at will. The semantic functor  $T_{S \triangleright P}$  has a universal property given by the following lemma.

**Lemma 4.** *Let  $P : S \rightarrow \mathbf{Sets}$  be a container. Then  $T_{S \triangleright P}$  is the left Kan extension of  $K_1$  along  $P$*

$$\begin{array}{ccc}
 S & \xrightarrow{P} & \mathbf{Sets} \\
 \downarrow K_1 & \searrow T_{S \triangleright P} = \mathbf{Lan}_P K_1 & \\
 \mathbf{Sets} & & 
 \end{array}$$

**Proof** We calculate as follows

$$(\mathbf{Lan}_P K_1)X = \int_{s:S} \mathbf{Sets}(Ps, X) \times K_1 s = \Sigma s : S. \mathbf{Sets}(Ps, X) = T_{S \triangleright P}(X)$$

where the first equality is the classic coend formula for coends, the second equality holds as  $S$  is a discrete category and  $1$  is the unit for the product, and the last equality is the definition of  $T_{S \triangleright P}(X)$ .  $\square$

As we shall see, this universal property will be vital to our representation theorem.

## 2.1 Container Morphisms

Containers are designed for implementation. Thus, we imagine defining lists in a programming language by writing something like

$$\text{data List} = (n : \mathbb{N} \triangleright \underline{n})$$

although the type dependency means we need a dependently typed language. If we were to do make such declarations, how should we program? The usual definition of lists based upon initial/final algebras give rise naturally to recursive forms of programming. We show that all polymorphic functions between containers are captured uniquely by *container morphisms*.

To understand these container morphisms, consider the effect of the reverse function on a list written in container form  $(n, f)$ . Its reversal must be a list and hence of the form  $(n', f')$ . In addition,  $n'$  should only depend upon  $n$  since reverse is polymorphic and hence shouldn't depend upon the actual data in the list given by  $f$ . Thus there is a function  $\mathbb{N} \rightarrow \mathbb{N}$ . In the case of reverse, the length of the list doesn't change and hence this is the identity. To define  $f'$  which associates to each position in the output a piece of data, we should first associate to each position in the output a position in the input and then look up the data using  $f$ . Pictorially we have:

Here we start with a list  $l_0$  which has 4 positions and a labelling  $f$  function into  $X$ . The result of reversing  $l_0$  is list with 4 positions with labelling function  $f'$  into  $X$  given by the above composite. In general, we therefore define

**Definition 5 (Container Morphisms).** A morphism  $(A \triangleright B) \rightarrow (C \triangleright D)$  consists of a pair  $(u, f)$  where  $u : A \rightarrow C$  and, for each  $a \in A$ , a map  $f_a : D(ua) \rightarrow Ba$ . The category of containers and container morphisms is written **Cont**

**Example 6** The reverse program is given by the container morphism  $(Id, f_n)$  where the function  $f_n : \{0, \dots, n-1\} \rightarrow \{0, \dots, n-1\}$  is defined by  $f_n(i) = n - i - 1$

Note how  $f_n$  says that the data stored at the  $i$ 'th cell after reversing a list is that data stored at the  $n - i - 1$ 'th cell in the input list. Here is an example of the tail function  $\text{tail} :: \text{List}(X) \rightarrow 1 + \text{List}(X)$ . The shapes of the datatype  $1 + \text{List}(X)$  is  $1 + \mathbb{N}$  with the shapes above  $\text{inl}(\ast)$  being empty while the shapes above  $\text{inr}(n)$  is the set  $\{0, \dots, n-1\}$ . We therefore write this container as  $(1 + n : \mathbb{N} \triangleright 0 + \underline{n})$ .

**Example 7** The tail function  $(u, f)$  is given by the container morphism  $(n : \mathbb{N} \triangleright \underline{n}) \rightarrow (1 + n : \mathbb{N} \triangleright 0 + \underline{n})$  is given by

$$u(0) = \text{inl}(\ast) \quad u(n + 1) = \text{inr}(n)$$

and, given  $n : \mathbb{N}$ , define  $f_0 = !$  and  $f_{n+1} : \underline{n} \rightarrow \underline{n+1}$  by  $f_{n+1}(i) = i + 1$ .

The last clause says that the  $i$ 'th cell in the output of a nonempty list comes from the  $i + 1$ 'th cell in the input list. The reader may like to check their understanding at this point by wondering what function is defined by setting  $f_{n+1}(i) = i$  in the above example. We finish this section with two final points. First, a categorical re-interpretation of a container morphism analogous to the categorical interpretation of a container  $A \triangleright B$  as a presheaf  $B : A \rightarrow \mathbf{Sets}$  as in lemma 4.

**Lemma 8.** A morphism of containers  $(u, f) : (A \triangleright B) \rightarrow (C \triangleright D)$  is given by a functor  $u : A \rightarrow C$  and the following natural transformation

**Proof** Since  $A$  and  $C$  are discrete categories, a functor is just a function. Since  $A$  is discrete, the natural transformation is just a family of maps of the given form.  $\square$

Finally, containers are more than just a tool to program with — they can also simplify reasoning. For example, consider the problem of proving that `reverse . reverse` is the identity. Using the usual recursive definition one soon runs into problems and one has to strengthen the inductive hypothesis to include properties reflecting the interaction of `reverse` and `append`. For the container definition, this problem is trivial as

$$(Id, f_n) \circ (Id, f_n) = (Id, f_n \circ f_n) = (Id, Id)$$

## 2.2 From Container Morphisms to Polymorphic Functions and Back

Given a container morphism  $(u, f) : (A \triangleright B) \rightarrow (S \triangleright P)$  does  $(u, f)$  really define a polymorphic function  $T_{A \triangleright B} \rightarrow T_{S \triangleright P}$ . And does it define all such polymorphic functions. And in a unique manner? To answer these questions we have to describe mathematically what a polymorphic function is. In the theory of program language semantics, covariant datatypes are usually represented as functors while polymorphic functions between

covariant datatypes are represented by natural transformations (5). Other representations of polymorphic functions are as terms in various polymorphic lambda calculi and via the theory of logical relations. Various theoretical results show that these are equivalent so in the following we take a polymorphic function to be a natural transformation.

Our key theorem is the following which ensures that our syntax for defining polymorphic functions as container morphisms is flexible enough to cover all polymorphic functions.

**Theorem 9.** *Container morphisms  $(A \triangleright B) \rightarrow (C \triangleright D)$  are in bijection with natural transformations  $T_{A \triangleright B} \rightarrow T_{C \triangleright D}$ . Thus, the functor  $T : \mathbf{Cont} \rightarrow [\mathbf{Sets}, \mathbf{Sets}]$  defines a full and faithful embedding of the category of containers into the category of endofunctors over  $\mathbf{Sets}$ .*

**Proof** The proof is a special case of the one we give later for quotient types in Theorem 19. Alternatively, see (2; 1)  $\square$

**Containers vs Shapely Types:** In (10) and (9) *shapely types* (in one parameter) in  $\mathbf{Sets}$  are pullback preserving functors  $F : \mathbf{Sets} \rightarrow \mathbf{Sets}$  equipped with a cartesian natural transformation to the list functor. Essentially, this means there are natural maps  $FX \rightarrow \text{List}(X)$  which extracts the data from an element of  $FX$  and places it in a list thereby obtaining a decomposition of data into shapes and positions similar to what occurs in containers.

Note however that the positions in a list have a notion of order and hence a shapely type is also equipped with an order on positions. Typically, when we declare a datatype we do not want to declare such an ordering over it and, indeed, in the course of programming we may wish to traverse a data structure with different orders. At a more theoretical level, by reducing datatypes to lists a classification theorem such as Theorem 9 would reduce polymorphic functions to polymorphic functions between lists but would not be able to classify what these are. Containers do not impose such an order and instead reduce datatypes to the more primitive idea of a family of positions indexed by a set of shapes.

### 3 Containers and Quotient Types

The purpose of this paper is to extend our previous results on containers to cover quotient datatypes and polymorphic functions between them. In particular we want to

- Generalise the notion of container to cover as many quotient datatypes as possible and thereby derive a syntax for declaring quotient datatypes.

- Define a notion of morphism between such generalised containers and thereby derive a syntax for polymorphic programming with quotient types.
- Prove the representation theorem for these polymorphic programs thereby proving that the quotient container morphisms really are polymorphic functions and that all such polymorphic functions are captured by quotient container morphisms.

### 3.1 Unordered Pairs and Cyclic Lists

We begin with an example of unordered pairs. Note first that the type  $X \times X$  is given by the container  $(1 \triangleright 2)$ . These are ordered pairs of elements of  $X$ . The type of unordered pairs of  $X$  is written as  $X \otimes X$  and is defined as  $X \times X / \sim$  where  $\sim$  is the equivalence relation defined by

$$\langle x, y \rangle \sim \langle y, x \rangle$$

Recall our analysis of the pair type was as one position, containing two shapes  $(1 \triangleright 2)$ . Lets call these positions  $p_1$  and  $p_2$ . An element of the pair type then consists of a labelling for these positions, ie a function  $f : \{p_1, p_2\} \rightarrow X$  for a set  $X$ . To move from unordered pairs to ordered pairs is exactly to note that the labelling  $f$  should be regarded the same as the labelling  $f \circ \text{swap}$  where  $\text{swap} : \{p_1, p_2\} \rightarrow \{p_1, p_2\}$  is the function sending  $p_1$  to  $p_2$  and  $p_2$  to  $p_1$ . Thus

**Example 10** *The type of unordered pairs of elements of  $X$  is given by*

$$(\{p_1, p_2\} \rightarrow X) / \sim$$

where  $\sim$  is the equivalence relation on  $\{p_1, p_2\} \rightarrow X$  obtained by setting setting  $f \circ \text{swap} \sim f$

Lets cement our intuitions by doing another example. A cyclic list is a list with no starting point. Here is a cyclic list of length 5

Can we represent cyclic lists in the same style as we used for unordered pairs? First recall that lists were given by

$$\text{List}(X) \equiv \Sigma n : \mathbb{N}. \{0, \dots, n-1\} \rightarrow X .$$

Now, in a cyclic list of length  $n$ , a labelling  $f : \{0, \dots, n-1\} \rightarrow X$  should be equivalent to the labelling  $f \circ \lambda_{i.(i+k) \bmod n}$  where  $k \in \{0, \dots, n-1\}$ . Thus we may define

**Example 11** *The type of cyclic lists of elements of  $X$  is given by*

$$\text{CList}(X) \equiv \Sigma n : \mathbb{N}. (\{0, \dots, n-1\} \rightarrow X) / \sim$$

where  $\sim$  is the equivalence relation setting on  $\{0, \dots, n-1\} \rightarrow X$  obtained by setting  $f \sim f \circ \lambda_{i.(i+k) \bmod n}$  where  $k \in \{0, \dots, n-1\}$ .

The observant reader will have spotted that, in example 11, there is actually an equivalence relation for each shape. However for clarity we leave this implicit. Also we will henceforth write  $A \rightarrow B / \sim$  rather than  $(A \rightarrow B) / \sim$  for equivalence classes of functions.

Examples 10 and 11 exemplify the kind of structures we wish to compute with, ie the structures for which we want to find a clean syntax supporting program construction and reasoning. In general they consist of a container as defined before with an equivalence relation on labellings of positions. To ensure the equivalence relation is structural, ie independent of data as one would expect in a polymorphic setting, the equivalence relation is defined by identifying a labelling  $f : P(s) \rightarrow X$  with the labelling  $f \circ \alpha$  where  $\alpha$  is one of a given set of isomorphisms on  $P(s)$ . Hence we define

**Definition 12 (Quotient Containers).** *A quotient container  $(S \triangleright P/G)$  is given by a container  $(S \triangleright P)$  and, for each shape  $s \in S$ , a set  $G(s)$  of isomorphisms  $P(s)$  closed under composition, inverses and containing the identity*

Thus a quotient container has an underlying container and, every container as in Definition 1 is a quotient container with an empty collection of isomorphisms. Another way of describing the isomorphisms in a quotient container  $(S \triangleright P/G)$  is to say that for each  $s \in S$ ,  $G(s)$  is a subgroup of the automorphism group on  $P(s)$ . Often we present a quotient container  $(S \triangleright P/G)$  by defining, for each shape  $s \in S$ , the group  $G(s)$  to be the smallest group containing a given set. However, the advantage of requiring  $G(s)$  to be a group is that if we define  $f \sim_G f'$  iff there is a  $g \in G(s)$  such that  $f = f' \circ g$ , then  $\sim_G$  is automatically an equivalence relation and so we don't have to consider its closure. A more categorical presentation of quotient containers reflecting the presentation of containers used in lemma 4 is the following

**Lemma 13.** *A quotient container is exactly a functor  $P : S \rightarrow \mathbf{Sets}$  where every morphism of  $S$  is both an endomorphism and an isomorphism*

**Proof** Given a quotient container  $(S \triangleright P/G)$ , we think of  $S$  as the category with objects elements  $s \in S$  and, as endomorphisms of  $s$ , the set  $G(s)$ . The functor  $P$  is then then

obvious functor mapping  $s$  to  $P(s)$ . □

Given a quotient container,  $(S \triangleright P/G)$ , of course we want to calculate the associated datatype or functor  $T_{S \triangleright P/G} : \mathbf{Sets} \rightarrow \mathbf{Sets}$ . As with the presentation of containers we do this concretely and then more abstractly to uncover a hidden universal property.

**Definition 14 (Extension of a Quotient Container).** *Given a quotient container, say  $(S \triangleright P/G)$ , its extension is the functor  $T_{S \triangleright P/G} : \mathbf{Sets} \rightarrow \mathbf{Sets}$  by*

$$T_{S \triangleright P/G}(x) = \Sigma s : S. (P(s) \rightarrow X) / \sim_s$$

where  $\sim_s$  is the equivalence relation on the set of functions  $P(s) \rightarrow X$  defined by  $f \sim f'$  if there is a  $g \in G(s)$  such that  $f' = f \circ g$

So a quotient container is like a container except that in the datatype it gives rise to, a labelling  $f$  of positions with data is defined to be the same as the labelling  $f \circ g$  obtained by bijectively renaming the positions using  $g \in G(s)$  and then performing the labelling  $f$ . The more abstract formulation is given by the next lemma which uses lemma 13 to regard a quotient container  $(S \triangleright P/G)$  as a presheaf  $P : S \rightarrow \mathbf{Sets}$

**Lemma 15.** *Let  $P : S \rightarrow \mathbf{Sets}$  be a quotient container. Then  $T_{S \triangleright P/G}$  is the left Kan extension of  $K_1$  along  $P$*

$$\begin{array}{ccc}
 S & \xrightarrow{P} & \mathbf{Set} \\
 \downarrow K_1 & \searrow & \\
 \mathbf{Set} & & T_{S \triangleright P} = \mathbf{Lan}_P K_1
 \end{array}$$

**Proof** We can calculate the left Kan extension as follows

$$\begin{aligned}
 (\mathbf{Lan}_P K_1)X &= \int_{s:S} \mathbf{Sets}(Ps, X) \times K_1 s \\
 &= \Sigma s : S. \mathbf{Sets}(Ps, X) / \sim \\
 &= T_{S \triangleright P}(X)
 \end{aligned}$$

where by first equality is the classic coend formula, the second is the reduction of coends to colimits and the third is the definition of  $T_{S \triangleright P/G}$ . This is because, the equivalence relation  $\sim$  in the coend has  $f \sim f'$  iff there is a  $g : s \rightarrow s$  such that  $f' = f \circ P(g)$  where  $f, f' : P(s) \rightarrow X$ . This is exactly the definition of the extension of a quotient container. □

The theory of containers thus generalises naturally to quotient containers as the same formula of left Kan extension calculates both the semantics of a container and that of a quotient container.

We finish this section on the presentation of quotient types with the example of finite bags as promised. Bags of other sizes are of course a straightforward generalisation. given this remark, we henceforth refer to finite bags as simply bags. The key intuition is that a bag is like a set but elements may have multiple occurrences - one may thus define a bag as  $\text{Bag}(X) = X \rightarrow \mathbb{N}$ . By putting all the elements of a bag in a list we get a representation of the bag but of course there are many such representations since there is no order of elements in the bag but there is in a list. Thus we get a bijection between bags and lists quotiented out by all rearrangements of positions. Hence

**Example 16** *The bag type is the quotient container  $(S \triangleright P/G)$  where  $(S \triangleright P)$  is the container for lists and, for  $n : \mathbb{N}$ , we take  $G(n)$  to be the set of all isomorphisms on the set  $\{0, \dots, n-1\}$*

## 4 Programming with Quotient types

We have identified a class of quotient data structures and axiomatised them as quotient containers. These quotient containers can be seen as datatype declarations in a programming language and so we now ask how we program polymorphically with these quotient containers.

Recall a container morphism  $(S \triangleright P) \rightarrow (Q \triangleright R)$  consisted of a translation of shapes  $u : S \rightarrow Q$  and, for each  $s \in S$ , a map  $f_s : R(us) \rightarrow P(s)$  sending positions in the output to positions in the input. If we now ask what is a map of quotient containers  $(S \triangleright P/G) \rightarrow (Q \triangleright R/H)$  its reasonable to require a map  $(u, f) : (S \triangleright P) \rightarrow (Q \triangleright R)$  of the underlying containers which takes into account the respective quotients. There are two issues

- Since the maps  $f_s : R(us) \rightarrow P(s)$  are labellings, the quotient given by  $H$  says that a quotient container morphism  $(u, f_s)$  is the same as another quotient container morphism  $(u, f'_s)$  if for each  $s \in S$ , there is an  $h \in H(us)$  such that  $f = f' \circ h$ .
- Given a map  $f_s : Q(us) \rightarrow P(s)$  and a  $g \in G(s)$  then the labellings  $f$  and  $g \circ f$  should be regarded as equal as labellings of  $Q(us)$ . Hence there should be an  $h \in H(us)$  such that  $f \circ h = g \circ f$ .

Hence we define

**Definition 17.** *A pre-morphism of quotient containers  $(S \triangleright P/G) \rightarrow (Q \triangleright R/H)$  is given by a morphism of the underlying containers  $(u, f) : (S \triangleright P) \rightarrow (Q \triangleright R)$  such that for each*

$g \in G(s)$ , there is an  $h \in H(us)$  such that

$$\begin{array}{ccc} Q(us) & \xrightarrow{f_s} & P(s) \\ h \downarrow & & \downarrow g \\ Q(us) & \xrightarrow{f_s} & P(s) \end{array}$$

The morphisms  $(S \triangleright P/G) \rightarrow (Q \triangleright R/H)$  are the premorphisms quotiented by the equivalence relation

$$(u, f) \sim (u, f') \text{ iff for all } s \in S, \text{ there exists } h \in H(us) \text{ such that } f_s = f'_s \circ h$$

Intuitively, the first condition is precisely the naturality of the quotient container morphism while the second reflects the fact that labellings are defined upto quotient. Is this a good definition of a polymorphic program between quotient containers? We answer them two ways. On a theoretical level we show that all polymorphic programs can be uniquely captured by such quotient container morphisms while on a practical level we demonstrate a number of examples.

**Lemma 18.** *The quotient container morphisms  $(S \triangleright P/G) \rightarrow (Q \triangleright R/H)$  are in one-to-one bijections with natural transformations  $K_1 \rightarrow T_{Q \triangleright R/H} P$  where in the latter we regard  $P : S \rightarrow \mathbf{Sets}$  as a presheaf as described in lemma 4.*

**Proof** Such natural transformations are exactly  $S$ -indexed maps  $K_1(s) \rightarrow T_{Q \triangleright R/H} P(s)$  which are natural in  $S$ . Thus we have maps

$$1 \rightarrow \Sigma q : Q. R(q) \rightarrow P(s) / \sim_H$$

which are natural in  $S$ . Such a family of  $S$ -indexed maps is exactly a map  $u : S \rightarrow Q$  and an  $S$ -indexed family of elements of  $R(us) \rightarrow P(s) / \sim$  natural in  $S$ . An element of  $R(us) \rightarrow P(s) / \sim$  is clearly a an equivalence class of functions while the naturality corresponds to the commuting diagram above  $\square$

**Theorem 19.** *Quotient container morphisms are in one-to-one bijection with natural transformations between their extensions. Hence there is a full and faithful embedding  $T : \mathbf{QCont} \rightarrow [\mathbf{Sets}, \mathbf{Sets}]$*

**Proof** Natural transformations  $T_{S \triangleright P/G} \rightarrow T_{Q \triangleright R/H}$  are by lemma 15 exactly natural transformations  $\text{Lan}_P K_1 \rightarrow \text{Lan}_R K_1$ . By the universal property of Kan extensions given at the beginning of section 2, these are in one-to-one bijection with natural transformations  $K_1 \rightarrow T_{Q \triangleright R/H} P$  which by lemma 18 are in one-to-one bijection with

quotient container morphisms  $(S \triangleright P/G) \rightarrow (Q \triangleright R/H)$  □

Notice the key role of the left Kan extension here. It identifies a universal property of the extension of a quotient container which is exactly what is required to prove Theorem 19. Also note that Theorem 9 is a corollary as there is clearly a full and faithful embedding of **Cont** into **QCont**

We now finish with some examples. Firstly, if  $(S \triangleright P/G)$  is a container and for each  $s \in S$  the group  $G(s)$  is a subgroup of  $H(s)$ , then there is a morphism of quotient containers  $(S \triangleright P/G) \rightarrow (S \triangleright P/H)$ . Thus

**Example 20** *The canonical maps  $\text{List}(X) \rightarrow \text{CList}(X) \rightarrow \text{Bag}(X)$  are polymorphic as, for a given  $n \in \mathbb{N}$ , they arise as container morphisms from the inclusions of the singleton group into the group of functions  $\{\lambda i. i + k \bmod n \mid k \in \{0, \dots, n-1\}\}$  and of this group into the group of all isomorphisms on  $\{0, \dots, n-1\}$*

**Example 21** *Every datatype given by a quotient container  $(S \triangleright P/G)$  has a map operation which is given by the action of functor  $T_{S \triangleright P/G}$  on morphisms*

**Example 22** *We can extend the operation of reversing a list to a reverse on cyclic lists. One simply needs to check the commutation condition that for each size  $n$  and  $k \in \{0, \dots, n-1\}$ , there is a  $k'$  such that*

$$\lambda i. (i+k) \bmod n \circ \lambda i. n-i-1 = \lambda i. n-i-1 \circ \lambda i. (i+k') \bmod n$$

*Of course we simply take  $k' = n-k-1$*

In general this shows how simple our theory is to apply in practise. We simply have one condition to check!

## 5 Conclusions and Further Work

We have provided a synthesis of polymorphism with quotient datatypes in such a way as to facilitate programming and reasoning with such quotient structures. This work is based upon an extension of our previous work on containers which, going further than shapely types, present datatypes via a collection of shapes and, for each shape, a collection of positions where data may be stored. The treatment of quotient datatypes is structural in that the quotient is determined by a collection of isomorphisms on these position sets which induce a quotient on the labellings of positions with data. On top of this presentation of datatypes, we have provided a means for programming

with such structures by defining morphisms of quotient containers. These are essentially morphisms of the underlying containers which respect the relevant quotients. This simple axiomatisation is proven correct in that we show that these morphisms determine exactly the polymorphic programs between these quotient data structures.

As for further work, we believe containers are an excellent platform for generic program and we wish to develop this application of containers. With specific relationship to these quotient containers, we have begun investigating their application to programming in the Theory of Species which was Joyal's motivation for developing analytic functors.
